[Received: 21 May 2017; Accepted: 18 July 2017]

Background: The proper palmar digital arteries arise infrequently from dorsal metacarpal arteries. This work reports the second dorsal metacarpal artery unusual ending and a vascular variation related to the superficial palmar arch.

Materials and methods: Fresh human upper limbs routine dissection, from a male cadaver, injected with coloured elastomeric material, immersed in 10% formalin.

Results: The second dorsal metacarpal artery presented terminal branches, the index finger medial proper digital palmar artery and the middle finger lateral proper digital palmar artery. At the division point of both terminal branches, the second dorsal metacarpal artery anastomoses with a thin forth common digital palmar artery.

Conclusions: The value of this knowledge about the infrequent vascular disposition lies in vascularised flaps design using the second dorsal metacarpal artery.

Key words: second dorsal metacarpal artery, proper palmar digital arteries, superficial palmar arch, vascularised flap

INTRODUCTION

The origin of the proper palmar digital arteries (PPDAs) in dorsal metacarpal arteries (DMAs) is an infrequent event. Adachi [1], Coleman and Anson [2], Earley [6] and Libersa et al. [14] mentioned this possibility, but they give only inaccurate references. The second dorsal metacarpal artery (2DMA) is important because it is the arterial vascular pedicle of the 2DMA flaps used to treat different injuries of hand and digits.

MATERIALS AND METHODS

Fresh male human cadaver, 64 years old. Right and left upper limbs were injected through brachial artery with elastomeric material using manual pressure, immersed in 10% formalin, and dissected using standard technique and 2 × magnification lenses.

RESULTS

In both hands the origin of 2DMA from the radial artery (RA) is found in the anatomical snuffbox. It passes under the extensor carpi radialis longus, surrounding the base of the second metacarpal bone, reaches the second interosseous space, between the extensors carpi radialis longus and brevis, giving muscular, osseous and cutaneous branches (Figs. 1, 2).

Following its path, it goes under the extensor indicis and the intertendinous connection between the...
index and middle finger. In the second web space, it follows as distal perforating artery and divides in the PPDAs medial of the index finger and lateral of the middle finger. In the point of division, it anastomoses with a very thin fourth common digital palmar artery (4CDPA).

In the right hand (Fig. 1), the first, second and third common palmar digital arteries (1, 2, 3CPDAs) originate from the ulnar artery, while the 4CPDA originates from the 3CPDA. This last artery, anastomoses with the superficial palmar branch of the radial artery (SPBRA), which gives two branches: one is an anastomotic thin branch with the radial PPDA of the thumb; the other branch, anastomoses with radialis indicis artery (RIA), a branch of the first metacarpal artery (1MCA). In the left hand (Fig. 2), the ulnar artery anastomoses with the 1MCA, at the origin point of a thin 4CPDA, similar to the right hand. The 4CPDA finishes with the 2DMA anastomosis at PPDAs division point.

**DISCUSSION**

The 2DMA, found in high percentages, originates from RA [3, 5, 6, 9, 20], dorsal carpal arch [1, 3, 7, 9, 12], deep palmar arch [4, 11], and anterior interosseous artery [7]. Following the second dorsal
H.F. Bianchi et al., Unusual ending of the second dorsal metacarpal artery as PPDAs

interosseous space from these different sources, gives branches to the dorsal skin of the hand, the skin of next fingers, and second metacarpal bone.

It arrives to the second web space and ends as distal perforating branch, anastomotic with branches from the deep palmar arch, which is mentioned by all the authors [1–5, 9, 17], except Earley [6], that found it only in four specimens. Yang and Morris [19] described the perforating branches with origin in the palmar metacarpal arteries.

Adachi [1] and Libersa et al. [14] mention the 2DMA as a source of PPDA; Edwards [8] suggested that this origin could be possible due existing anastomoses at the second web space, but in his series of specimens, he did not find it. Coleman and Anson [2] described its presence limited to the first and second digital web spaces. In these papers, there are no images, drawings or schemes illustrating the descriptions.

In our study, the 4CPDA was found to be a small blood vessel in contrast with the well-developed 2DMA. Additional finding was the lack of a second palmar metacarpal artery, which compensated the low contribution of the 4CPDA.

We share the opinion of Rodríguez-Niedenführ et al. [16] regarding the development of arteries that they came from buds, initial capillary plexuses, and differentiate from proximal to distal, process that turns them into definitive blood vessels, while others disappear or undergo an incomplete development. In our case, the 4CPDA is insufficient to give the fingers blood supply and the 2PMA, that supplies the last artery, is absent (possible regression as suggested by Rodríguez-Niedenführ et al. [16]); therefore the 2DMA is increased in size to compensate the 4CPDA and becoming in the dorsal origin of the PPDA, as established by Edwards [8].

One more time, we can appreciate variations in blood vessels in the radial side of the hand as described by Edwards [8]. In the right hand, a superficial palmar arch is composed of the anastomoses between the superficial palmar branch of the radial artery (SPBRA) and the 4CPDA, which originates in the 3CDPA. Because of this vascular pattern, the superficial arch could be considered as complete but indirect, because the anastomoses exist, but between the SPBRA and a collateral branch of the ulnar superficial

artery. Literature about this anatomical disposition described above was not found.

The use of the second dorsal metacarpal artery flap is a technique widely used, to cover damage areas of hand or fingers because of the high presence of the artery (93–100%) [6, 8, 9]. We can design it as a proximal or distal vascularised cutaneous flap [3–5, 7, 9, 12, 15, 20] or as a vascularised bone flap [3, 13]. Regardless of flap type, the 2DMA or the distal perforant artery must be ligated [12, 20]. In this case, this manoeuvre can be dangerous for the circulation of index and middle fingers, if 4CPDA, or another artery, is not sufficiently developed to compensate the blood supply lost. There are reports using 2DMA as a vascular pedicle, in the index pollicisation in case of congenital thumb aplasia [18].

The eco-Doppler examination is advised prior to the surgery [4, 5, 9, 10] because of the variations of the metacarpal dorsal arteries. The variation described in this case will be easy to detect, if this recommendation is followed, avoiding surprises at the moment to design the flap or planning surgery.

We were unable to find accurate descriptions of this vascular pattern in the literature, except inaccurate references without any kind of illustration. The development of vascularised flaps with the 2DMA requires the knowledge of anatomical variations of the origin and course of this artery and its connections with the superficial and deep palmar arches, no matter if they are, fortunately, of low incidence.
